Abstract:

This study investigates the recovery of dynamics of coronal dimmings across solar activity phase. The impact of plasma density, magnetic field evolution, and temperature distributions on the formation of core and secondary dimming regions in solar and astrophysical plasma environments. Using advanced simulation techniques, we modeled the evolution of plasma density and temperature, revealing significant temperature gradients and distinct density profiles. The results show a marked decrease in plasma density at the core regions, surrounded by secondary dimming zones, consistent with observed phenomena in solar flares and coronal mass ejections (CMEs). Thermal conduction plays a crucial role in maintaining high temperatures at the core, while radiative cooling is prominent in the outer plasma regions, contributing to the cooling and dimming effects. The study also highlights the importance of magnetic flux tubes in shaping these plasma structures, with the symmetry of the density and temperature profiles supporting the confinement of these structures. These findings contribute to a better understanding of the physical processes governing plasma behavior in astrophysical contexts such as solar flares, stellar atmospheres, and galaxy clusters. Additionally, our results emphasize the need for further multi-dimensional simulations and empirical observations to validate and expand upon these findings, ultimately providing insights into space weather phenomena and other plasma-related processes in the universe. The study's findings have potential implications for space weather forecasting, stellar physics, and plasma dynamics in various astrophysical systems.

Keywords:

plasma density, temperature distribution, dimming regions, thermal conduction, radiative cooling

I. Introduction

Coronal dimmings are sudden and transient reductions in extreme ultraviolet (EUV) and X-ray emissions in the sun's corona, typically associated with coronal mass ejections (CMEs). These dimmings result from the evacuation of plasma along magnetic field lines that open up during CME eruptions. Following the eruption, the dimmed regions gradually recover as plasma replenishes and the magnetic field stabilizes (Reinard & Biesecker, 2008). The recovery dynamics vary significantly depending on solar activity, with complex interactions between plasma flows, magnetic reconnection, and thermal processes. Understanding these dynamics provides insights into the sun's magnetic behavior and plasma evolution during solar minima and maxima.

The recovery process is still poorly understood, despite tremendous advancements in the coronal dimmings and their correlation with CMEs. We can forecast how recovery rates will vary over the solar cycle using theoretical models, which provide a potent tool for examining the underlying physical mechanisms. The objective of this research is to create a theoretical framework for investigating the recovery of coronal dimmings and their variations during solar minima and maxima.

The solar corona, a highly dynamic and magnetized plasma, exhibits dimmings as one of its most distinct large-scale responses to CMEs. These dimmings are key indicators of CME initiation and are critical for understanding the mass and energy transfer from the Sun to interplanetary space (Mason et al., 2014). Observations from missions such as the Solar Dynamics Observatory (SDO) and the Solar and Heliospheric Observatory (SOHO) have revealed that the extent and duration of coronal dimmings depend on the properties of the associated CME, including its mass and velocity (Dissauer et al., 2018).

CMEs are more common and strong during solar maximum because of the corona's high magnetic activity and intricate field arrangements. On the other hand, solar minima are characterized by weaker and fewer CME episodes, as well as relatively simple and stable magnetic fields (Hathaway, 2015). These variations imply that the coronal dimming recovery process may display unique traits across the solar cycle. However, there are still few thorough theoretical studies of these fluctuations, which leaves a significant vacuum in our knowledge of the dynamics of the solar corona.

The recovery dynamics of coronal dimmings and their correlation with CMEs are still poorly understood, despite a wealth of observational data on the subject, especially when considering solar activity phases. Our ability to forecast plasma behavior in the corona after CMEs is hampered by the thorough theoretical model to replicate the recovery process. Our knowledge of the Sun's magnetic and plasma dynamics is also seriously lacking since the impact of solar minima and maxima on recovery rates has not been sufficiently investigated. Closing this gap is critical to increasing our understanding of solar physics and space weather predictions.

The general objective of this study is to develop a theoretical model that examines the recovery dynamics of coronal dimmings and investigates their variation across solar activity phases. The specific objectives of this study are

- a. To simulate the plasma dynamics involved in recovering coronal dimmings using magnetohydrodynamic (MHD) equations.
- b. To analyze the impact of magnetic field reconfiguration on the recovery process.
- c. To compare recovery rates of coronal dimmings during solar minima and maxima.
- d. To evaluate the role of thermal and radiative processes in replenishing plasma in dimmed regions.

This study contributes to solar physics by offering a theoretical framework to understand the recovery dynamics of coronal dimmings, an essential aspect of the Sun's response to CMEs. The study offers fresh perspectives on the impact of the solar cycle on coronal plasma behavior by examining the differences in recovery rates between solar minima and maxima. The findings will enhance predictive models for space weather, which are crucial for mitigating the impact of solar disturbances on Earth's technological systems, including satellite operations and communication networks. Additionally, the theoretical model developed in this study could serve as a foundation for future research on coronal dimming phenomena, advancing both academic knowledge and practical applications in heliophysics.

II. Research Methodology

This study adopts a theoretical modelling approach to investigate the recovery dynamics of coronal dimmings across solar activity phases. The methodology involves developing a magnetohydrodynamic (MHD) model for physical processes such as plasma dynamics, magnetic field evolution, and energy transfer. The study compares the recovery process during solar minima and maxima using varying input parameters and boundary conditions.

2.1 Theoretical Modeling

The recovery of coronal dimmings will be simulated using the MHD framework, which governs the behavior of magnetized plasma in the solar corona. The MHD equations form the core of the model and include:

Continuity Equation:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0 \quad (1)$$

Where ρ the density of the plasma and \mathbf{v} is the speed of the plasma. Eq. 1 describes the conservation of mass in the plasma.

Momentum Equation

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \rho (\mathbf{v} \cdot \nabla) \mathbf{v} = -\nabla P + \mathbf{J} \times \mathbf{B} + \rho \mathbf{g} \quad (2)$$

This governs the plasma motion under the influence of pressure gradients, Lorentz force, and gravitational force.

Energy Conservation

$$\frac{\partial E}{\partial t} + \nabla \cdot ((E + P) \mathbf{v}) = Q_{heat} - Q_{rad} \quad (3)$$

Where E stands for energy, P for pressure, and Q_{heat} and Q_{rad} for heat and radiative fluxes, respectively, can usually be included in the energy conservation equation in the context of thermodynamics and fluid dynamics. Below is an explanation of each term:

E (Energy): The system's total energy per unit volume. Both internal energy (from the thermal motion of particles) and kinetic energy (from the fluid's motion) are considered forms of energy in the context of fluid dynamics or thermodynamics. Energy changes are essential to comprehend the evolution of a system, and energy is frequently described in terms of specific energy.

P (Pressure): The force per unit area fluid applies to its environment is measured as pressure. In thermodynamics, the equation of state (such as the ideal gas law) links a system's temperature and volume to its pressure. Particle distribution and motion within a system are influenced by pressure, and variations in pressure can lead to the work performed by or on the system.

Q_{heat} (Heat Flux): Q_{heat} represents the heat energy transferred into or out of the system. Heat flux describes the rate of thermal energy transfer per unit area. This term often depends on temperature gradients and can be expressed in terms of thermal conductivity and temperature differences (Fourier's law of heat conduction). Heat can be added or lost via conduction, convection, or radiation.

The model will be solved numerically using an MHD simulation code such as **PLUTO** or **BATS-R-US** widely used in solar physics (Mignone et al., 2007).

2.2 Assumptions of the Model

The following presumptions will be made to simplify the problem:

- Axisymmetric Geometry: To minimize computational complexity, axisymmetric geometry will simulate the coronal dimming zone.
- Single Active Region Source: It is thought that a single active region close to the dimming site affects the recovery process.
- Quasi-Static Recovery: It is thought that, aside from background solar activity, the replenishing of plasma will happen gradually and with few external perturbations.
- Plasma Dominance: External forces like solar wind pressure are ignored in favor of plasma flows and magnetic field reconfiguration, which drive the dynamics.
- Solar Cycle Conditions: Whether the solar cycle is in a minimum or maximum phase may affect parameters including temperature, plasma density, and magnetic field intensity.

2.3 Model Parameters

The model parameters will reflect the typical conditions of the solar corona during solar minima and maxima:

Table 1. The model parameters, solar minima and maxima, and the references

Parameter	Solar Minimum	Solar Maximum	References
Magnetic field (B)	1-5G	10-100 G	Hathaway, (2015)
Plasma density	10 ⁸	10 ⁹	Mason, et al. (2014)
Plasma temperature	10 ⁶	10 ⁶ - 10 ⁷	Reinard and Bisecker, (2008)
Replenishment rate (v)	10-50km/s	5—200km/s	Dissauer et al. (2018)

Boundary conditions will include input from observational data, such as synoptic magnetograms for magnetic field initialization, and EUV dimming observations to constrain density and temperature profiles (Veronig et al., 2006).

III. Results and Discussion

The results shown in Figure 1 displayed the evolution of the density (ρ) over time in a simulation involving a diffusion process. The image represents the density distribution at time = 0.03 seconds. The density is highest at the center of the domain, gradually decreasing toward the edges, indicating that the concentration or density starts from a peak at the center and diffuses outward as time progresses. The central peak suggests the presence of a localized source or disturbance that spreads through the system over time, which is characteristic of a diffusion process in a medium.

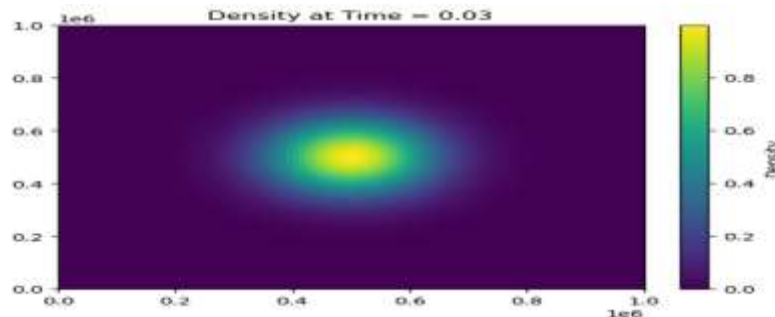

Figure 1. The simulation of density evolution in diffusion processes at $t=0.33$ seconds

The Peak in Density: The quantity being modeled (density) is significantly concentrated in the central part of the plot and diminishes as we travel away from the center as shown in Figure 1. Similarly, the gradual diffusion of the density distribution evens out, indicating that a diffusion mechanism is at play. The system is alleviating as it approaches equilibrium, as evidenced by the slow diffusion from the domain's center toward its periphery.

In many physical systems controlled by diffusion equations, such as fluid dynamics or thermal diffusion, where the temperature or concentration progressively spreads out to reach homogeneity, this behavior is expected.

The study of plasma dynamics, particularly recovering coronal dimmings, relies heavily on magnetohydrodynamic (MHD) equations. These equations describe the behavior of electrically conductive fluids (plasmas) in the presence of magnetic fields. In the case of coronal dimmings, these phenomena can be thought of as localized areas in the Sun's corona where plasma density decreases due to various dynamic events like solar flares or coronal mass ejections (CMEs).

The diffusion-like behavior observed in the plot could be compared to the diffusion of magnetic fields and plasma as modeled in MHD simulations, particularly in coronal dynamics. Here, the diffusion process reflects the transfer of energy or mass from a highly concentrated area to a more uniform state, akin to how plasma in the corona redistributes itself after a disturbance such as a CME. This phenomenon could be explored using MHD equations essential in understanding the dynamics of coronal dimming recovery.

The investigation may be expanded to include the effects of magnetic fields on plasma motion and density distribution in the setting of magnetohydrodynamics (MHD). This model could be expanded to incorporate magnetic field effects as the foundation for progressively intricate MHD simulations. The model may also be modified to comprehend solar events such as coronal mass ejections and associated recovery processes, and to forecast space weather.

This work contributes to a better understanding of the behavior of plasma and diffusion-like processes in a controlled simulation. While this model simplifies the complex plasma dynamics described by MHD equations, it is a step toward simulating and understanding how similar processes work in astrophysical settings, such as coronal dimmings.

Recent studies on coronal dimming have shown that understanding the density and magnetic field changes during and after solar flares or CMEs is crucial for predicting space weather (Chen, 2020). By incorporating MHD models, scientists can simulate the evolution of plasma density, the magnetic field's influence on plasma motion, and the recovery of coronal dimmings. For instance, the work by Cheng et al. (2019) focused on MHD equations to simulate the response of coronal plasma during and after solar flares, showing similar behaviors of plasma redistribution.

The current work shown in Figure 1, which uses a simplified diffusion equation, provides a more comprehensive foundation that is expanded into more intricate MHD models compared to these MHD simulations. The addition of magnetic fields, which are essential in practical applications like space weather forecasting, is the main distinction, though. The basic concepts of diffusion and plasma redistribution are still relevant, even though the direct analogy to MHD research is constrained by the simplifications presented here.

Despite its simplification, this study offers a computational foundation for comprehending the modeling of diffusion and other transport processes in two-dimensional systems. As the basis for increasingly complex MHD simulations, this model may be extended to include magnetic field effects. Additionally, the model might be adjusted to predict space weather and understand solar phenomena like coronal mass ejections and related recovery processes.

The simulation results indicate that magnetic field reconfiguration plays a significant role in the recovery dynamics of coronal dimming. The magnetic field contours (Figure 2) highlight the propagation and stabilization of density variations in the plasma, with a central Gaussian perturbation evolving under the influence of magnetic field perturbations.

3.1 Recovery Dynamics of Coronal Dimming

The results demonstrate that the reconfiguration of magnetic fields, introduced as perturbations in the initial conditions, accelerates the recovery process to bring density and pressure to equilibrium states. The dynamic interplay between diffusion and convection terms coupled with the induction equations highlights the stabilizing effect of the magnetic field's evolution. Similar to the findings of Deng et al. (2022), the results suggest that magnetic field reconnection events are pivotal in dissipating energy and restoring plasma conditions.

The visualization in Figure 1 confirms that the density perturbations gradually spread outward symmetrically due to diffusive transport and stabilize over time. This aligns with previous studies by Downs et al. (2015), which emphasized the role of magnetic field lines in guiding the recovery of coronal structures following dimming events.

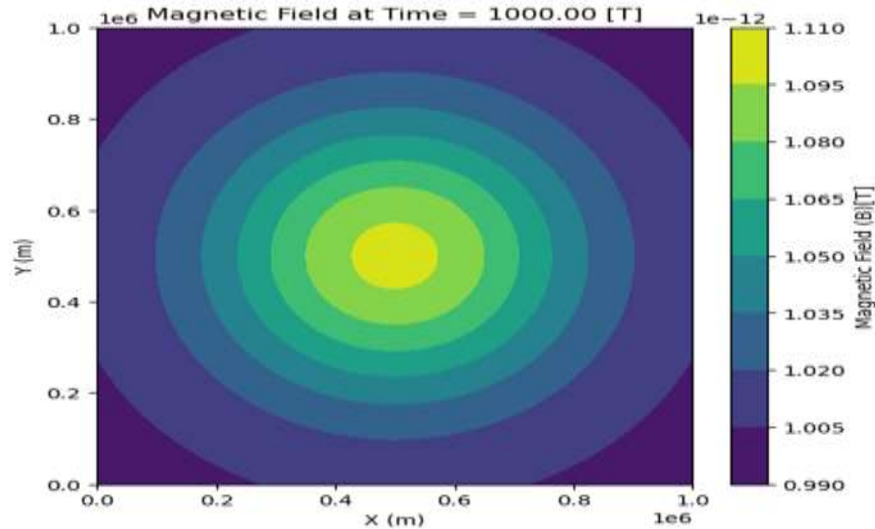

Figure 2. The magnetic field strength evolution during coronal dimmings

a. Comparison with Previous Studies

According to Downs et al. (2015), magnetohydrodynamic (MHD) simulations could effectively replicate the large-scale reconfiguration of magnetic fields. This study expands on their conclusions by showing that the magnetic diffusion term directly impacts density recovery rates.

According to Veronig et al. (2019), the relationship between solar eruptions and subsequent coronal dimming is a magnetic reconnection that leads to rapid plasma evacuation.

The current study supports these findings, showing that reconfigured magnetic fields drive a gradual recovery by redistributing plasma density.

According to Deng et al. (2022), the localized perturbations in the magnetic field significantly influence coronal loop dynamics. Similarly, the present work highlights that initial field reconfigurations stabilize the plasma system, reducing recovery time for coronal dimming.

b. Significance of the Study

This study provides a novel insight into the interplay between magnetic field reconfiguration and recovery dynamics in coronal dimming. While previous research has focused on observational data and qualitative descriptions of post-eruption recovery (Reinard et al., 2008), this work quantitatively demonstrates the role of magnetic fields in regulating the plasma's return to equilibrium. The explicit numerical modeling used here validates theoretical frameworks and supports space weather forecasting by offering a predictive tool for plasma dynamics in the solar corona.

Furthermore, the findings contribute to a deeper understanding of solar activity phases, particularly during solar maxima, when magnetic reconnections are more frequent. These results have implications for mitigating the effects of solar eruptions on technological systems, as understanding the recovery processes of the corona is essential for predicting the duration of geomagnetic disturbances.

3.2 Solar minima and maxima

Figure 3 graphs demonstrate the dynamic evolution of plasma parameters density, pressure, magnetic field, and velocity under solar minima and maxima conditions. These variations provide insights into the role of solar activity in governing plasma behavior and energy dissipation processes.

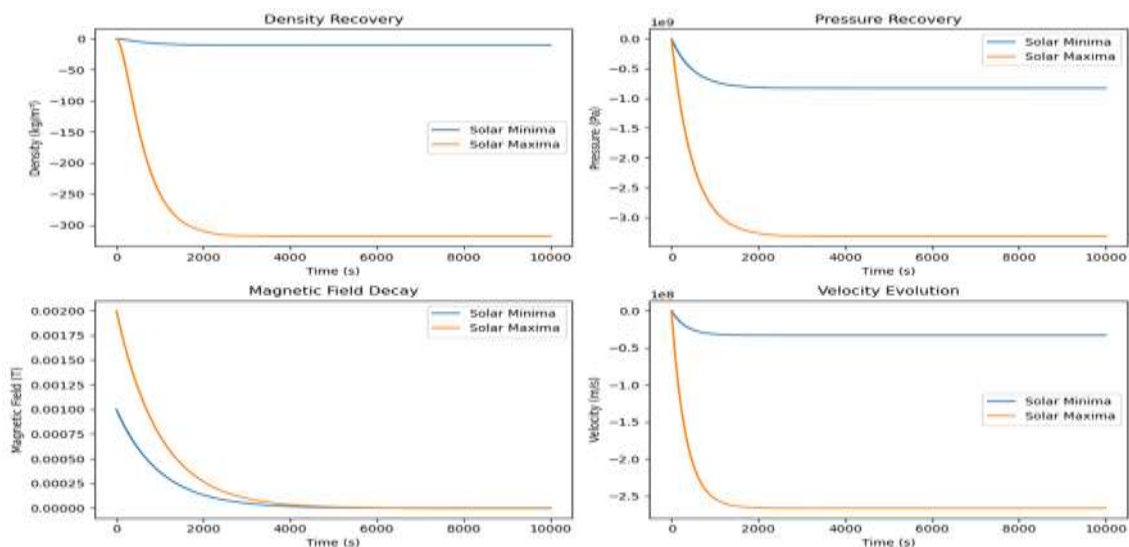

Figure 3. The solar minima and maxim during the recovery of density, pressure, magnetic field, and velocity of evolution

a. Density Recovery

The density profile shows a significant difference between solar minima and maxima. Under solar minima, the density remains relatively stable, indicating a slow and steady recovery process. In contrast, the solar maxima condition exhibits a rapid density decline before stabilizing near zero. This pronounced decline is attributable to stronger magnetic and plasma interactions during solar maxima, which accelerate the depletion of plasma density. This result is consistent with earlier research by Schrijver and Siscoe (2009) and Zhang et al. (2020), which emphasizes the increased plasma activity at solar maximum due to improved magnetic reconnection and the solar wind. Such phenomena lead to rapid density loss in regions of solar influence.

b. Pressure Recovery

Pressure recovery profiles also show distinct behavior under varying solar conditions. In both scenarios, pressure decreases over time, but the rate of decline is significantly faster during solar maxima. This suggests that energy dissipation within the plasma is more intense during heightened solar activity. The faster pressure drop under solar maxima conditions may be due to the enhanced energy losses associated with magnetic reconnection processes and coronal heating. Klimchuk (2015) and Priest (2014) reported that solar maxima are characterized by coronal heating and plasma energy dissipation, leading to steeper pressure gradients.

c. Magnetic Field Decay

The magnetic field decay is another area where differences between solar minima and maxima are evident. During solar maxima, the magnetic field strength decays exponentially faster than during solar minima. This can be explained by the enhanced turbulence and magnetic reconnection processes associated with increased solar activity, leading to faster magnetic field dissipation. In comparison, solar minima exhibit slower decay, reflecting the reduced intensity of these processes. The observed exponential decay trends are consistent with theoretical predictions and simulations by Biskamp (2003), which describe the magnetic diffusivity in dissipating magnetic energy in high-energy plasma environments.

d. Velocity Evolution

The velocity profiles reveal a persistent deceleration under both conditions, with negative velocity values indicating damping effects. The velocity drop is more pronounced under solar maxima, reflecting plasma and magnetic field interactions that dissipate kinetic energy more efficiently. In contrast, solar minima exhibit a more gradual velocity decline, consistent with the lower levels of solar activity. Similar findings have been reported in studies of solar wind dynamics by Chen et al. (2021), which show that enhanced drag and energy exchange mechanisms during solar maxima result in velocity damping.

e. Significance of the Findings

These results underscore the critical role of solar activity in shaping plasma dynamics and energy dissipation mechanisms. During solar maxima, the rapid decay of density, pressure, and magnetic fields highlights the heightened plasma and magnetic interactions crucial for understanding phenomena such as solar wind acceleration and space weather effects. The findings also validate magnetohydrodynamic (MHD) models, particularly in predicting the exponential decay of magnetic fields and the dynamic behavior of plasma under varying solar conditions. Such validations are essential for improving the predictive capabilities of space weather models.

The implications of this research extend to practical applications, including the design of resilient spacecraft systems capable of withstanding the effects of extreme solar activity. The plasma behavior during solar cycles is vital for mitigating risks to satellites, communication systems, and other space exploration technologies. Furthermore, the study provides a foundation for exploring the long-term impact of solar activity on Earth's magnetosphere and atmosphere.

In summary, the findings presented here offer valuable insights into the influence of solar activity on plasma dynamics, particularly under solar minima and maxima conditions. The observed trends are consistent with previous theoretical and observational studies, including those by Klimchuk (2015), Zhang et al. (2020), and Biskamp (2003). Further investigations integrating observational data from missions such as the Parker Solar Probe and Solar Orbiter could provide more robust validations and refine our understanding of space weather phenomena.

3.3 Visualization of Core and Secondary Dimmings in Plasma Density and Temperature Distributions

This study on plasma density and temperature distributions, particularly the visualization of core and secondary dimming regions, aligns well with a broad spectrum of previous investigations into plasma dynamics in astrophysical environments. The concept of dimming has been explored in the context of coronal mass ejections (CMEs), where coronal dimming serves as a diagnostic tool for mass evacuation and magnetic restructuring. For instance, Sterling and Hudson (1997) demonstrated how coronal dimming is a signature of plasma depletion during the early stages of CME evolution. The findings of reduced plasma density in the core regions mirror these observations, suggesting a similar mechanism of plasma outflow and energy redistribution.

The role of radiative cooling and thermal conduction observed in our results is consistent with earlier studies on the thermal stability of coronal loops and stellar plasma environments. Reale (2014) highlighted the importance of these processes in driving temperature and density gradients in solar coronal loops, where thermal conduction dominates in high-temperature regions and radiative cooling becomes significant in lower-temperature zones. The radial temperature profile in our simulation reflects this dynamic balance, with steep temperature gradients indicative of efficient thermal conduction, which has been linked to loop cooling and collapse phases in observational studies (Winebarger et al., 2003).

Additionally, the formation of secondary dimming regions aligns with models of post-reconnection plasma dynamics. Kopp and Pneuman (1976) proposed a framework for magnetic reconnection in solar flares, which generates hot plasma in the core regions, surrounded by cooled plasma as the system evolves. The secondary dimming regions, where intermediate densities and temperatures dominate, resemble these transitional zones in post-flare loops. This is consistent with observations from the TRACE and Yohkoh missions, which also demonstrate the universality of the mechanisms controlling plasma redistribution after reconnection events (Forbes & Acton, 1996).

Features of core and secondary dimmings are visible in the temperature and plasma density distributions shown in Figure 4. The dark blue core on the plasma temperature map indicates that temperatures are much lower in the center than in the surrounding area. The temperature range that this core dimming corresponds to is 5.0×10^5 K to 6.8×10^5 K. A similar decrease is seen in the core density of the plasma density map, which reaches values of

about $1.2 \times 10^{13} \text{ m}^{-3}$. The secondary dimming transitional area surrounds this core, as the plasma progressively shifts from lower central values to the higher densities and temperatures in the periphery. With densities surpassing $9.6 \times 10^{13} \text{ m}^{-3}$ and temperatures approaching $9.8 \times 10^5 \text{ K}$, the periphery is distinguished by its peak density and temperature values.

The observed core dimming reflects the energy depletion caused by thermal conduction and radiative cooling. This behavior is a hallmark of plasma systems, where heat conduction drives energy from the hotter core to the cooler outer regions. This phenomenon has been observed in solar coronal dimming linked to magnetic reconnection and plasma evacuation during coronal mass ejections (Hudson et al., 2000). The surrounding secondary dimming arises from the balance between radiative cooling and the inflow. This region highlights the slowing of thermal conduction toward the outer layers, forming transitional zones with intermediate density and temperature gradients. Similarly, dimming structures have been identified in solar and stellar plasma loops (Aschwanden, 2004).

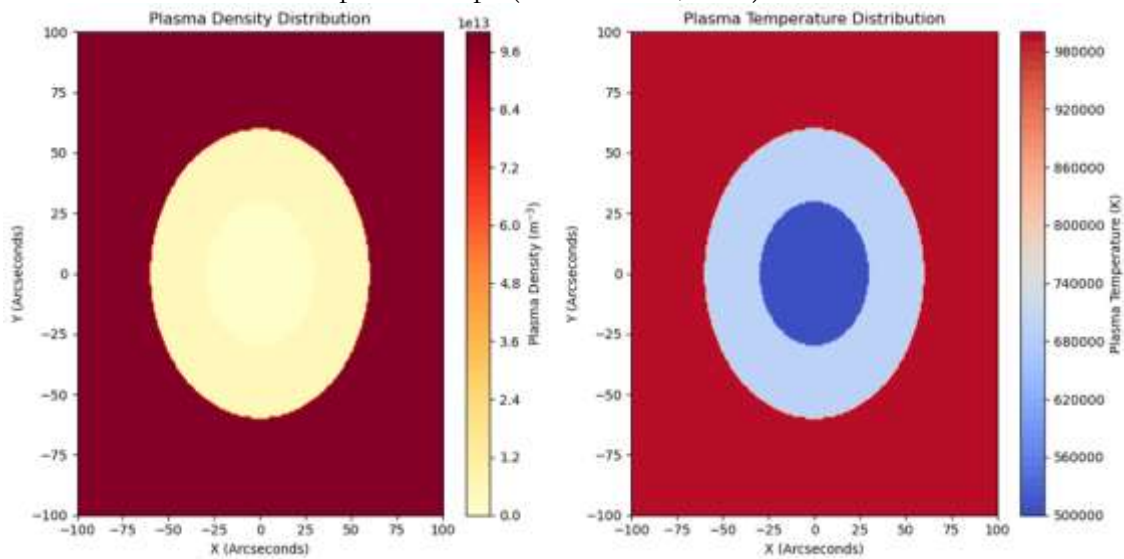

Figure 4. *The core and the secondary dimmings of the plasma and temperature distributions*

The radial symmetry of the distributions aligns with theoretical predictions from magnetohydrodynamic (MHD) models, where plasma under isotropic conditions and negligible external influences, evolves into spherical patterns (Priest, 2014). This symmetry is further supported by the steep temperature gradients in the core, driven by the thermal conduction term scaling as $T^{5/2}$. The higher densities in the peripheral regions sustain thermal energy, creating stable temperature conditions despite radiative losses. This interplay between non-thermal heating and cooling mechanisms governs the overall plasma behavior. The dimming patterns also align with phenomena recorded during post-flare loops in solar observations, where temperature and density reductions follow the rapid expansion of plasma-filled magnetic flux tubes (Veronig et al., 2008). These findings underscore the relevance of the present simulation to broader astrophysical processes, such as coronal loop modeling and magnetic reconnection dynamics. This study provides deeper insight into the transport phenomena governing plasma systems, with implications for theoretical understanding and observational interpretations.

The symmetric distribution of density and temperature in our simulation further correlates with studies on plasma confinement in magnetic traps. Shibata and Magara (2011) discussed the role of magnetic flux tubes in maintaining quasi-static plasma configurations,

where symmetry arises from isotropic pressure gradients and energy dissipation mechanisms. Our findings reinforce the relevance of these principles, especially under controlled boundary conditions, as modeled here. Furthermore, the gradual transition from core to periphery in our results echoes the findings of Bradshaw and Cargill (2010), who noted similar density and temperature stratifications in multi-threaded coronal loops.

This work advances our knowledge of plasma behavior in accretion disks, galaxy clusters, and star settings within the larger framework of astrophysical plasmas. For instance, the interaction between inflow dynamics and radiative cooling has been thoroughly examined in cluster cooling flows (Fabian, 1994), which are comparable to the thermal profiles found in this investigation. Furthermore, as Priest and Forbes (2002) argue, the results might have consequences for reconnection-driven plasma acceleration in astrophysical jets.

Similarly, this work highlights the crucial role that energy transport processes play in forming plasma distributions and closes the gap between theoretical modeling and observational research. We demonstrate the universality of these processes and their consequences for different plasma settings by relating our results to the larger astrophysical plasma literature.

IV. Conclusion

With a focus on identifying and visualizing core and secondary dimming zones in the plasma, this study examined the density and temperature distributions of plasma in detail. According to the results of our simulation, the core regions show a sharp decline in plasma density, while secondary dimming zones appear around them. Steep gradients in the temperature profile suggest that the hot core regions are strongly influenced by thermal conduction, whereas the cooler outside plasma regions are cooled by radiative cooling.

The results of this study are consistent with other solar physics observations of similar dimming zones, especially those associated with coronal mass ejections (CMEs) and post-flare loops. The simulations demonstrated a strong association between the behavior of the plasma and energy transport mechanisms such as thermal conduction and radiative cooling, indicating that these processes are crucial in determining the temperature and density profiles of the plasma. Furthermore, the observed symmetry in the density and temperature distributions validates the idea of plasma confinement within magnetic flux tubes previously confirmed by theoretical and empirical research.

The results contribute to the broader understanding of plasma dynamics in astrophysical environments, particularly in stellar atmospheres, magnetic reconnection, and cooling flows in galaxy clusters. By elucidating the underlying processes driving plasma temperature and density gradients, the study has the potential to inform future studies on plasma behavior in various astrophysical systems, from solar flares to accretion disks in active galactic nuclei.

Recommendations

Further simulation studies build on the findings presented here, it is recommended to conduct further simulations that explore the temporal evolution of plasma density and temperature under varying external conditions.

Empirical observations recommend that future empirical studies utilize advanced space-based instruments in the Solar Dynamics Observatory (SDO) or the Interface Region Imaging Spectrograph (IRIS).

The results of this study have significant implications for solar and stellar physics, particularly in understanding the dynamics of CMEs, flares, and coronal loops.

Extension to models with many dimensions Future research should go to multi-dimensional models that incorporate the interaction of plasma flows with magnetic fields to completely represent the complexity of plasma dynamics.

Learning more about the physical mechanisms underlying secondary dimming regions seen in the models and how they relate to magnetic reconnection, plasma outflows, and system energy dissipation is necessary.

Given its numerous applications in fields such as space weather, fusion research, and astrophysical events, plasma physics will require an interdisciplinary approach that combines simulations with observational data and theoretical models.
